(Received 6 December 2012; accepted 4 May 2013; published online 24 May 2013)

We introduce a chiral metamaterial with strong, non-resonant optical activity and very low polarization ellipticity. We achieve this by combining a meta-atom and its complementary structure into a meta-molecule, resulting in the coupling of magnetic and electric dipole responses. In contrast to either a pair of crosses or complementary crosses, this structure has low dispersion in the optical activity at the transmission resonance. We also study the excitation mechanism in this structure and optimize the optical activity through changing the twist angle. © 2013 AIP Publishing LLC.

A chiral structure is distinct from its mirror image, which causes the degeneracy between the right- and left-handed circularly polarized waves in the structure to be broken. This is due to cross-coupling between the magnetic and electric polarizations of the media at resonance, resulting in optical activity and circular dichroism.1 The response in metamaterials is much stronger than that in natural materials.

Three-dimensional structures, such as the helix or canonical spiral, can result in coupled magnetic and electric dipole type responses, due to the currents around the loops and along the structure.2 However, three-dimensional structures are difficult to fabricate, especially when scaled down for use at terahertz and optical frequencies.

Alternatively, by combining two or more achiral, planar elements, such as crosses3 or split ring resonators (SRRs),4 rotated about their common axis, a chiral meta-atom can be created. Such configurations have been shown to exhibit strong optical activity and broadband polarization conversion.3–6 It is known that the strong, near-field response between neighboring meta-atoms is important in determining the properties of the metamaterial.7,8 This is also the case in chiral structures formed from achiral constituents, where the near-field interaction is essential for determining the overall response of the material.6,9 The coupling effects between multiple such chiral structures have also been studied.10,11

Depending on the resonant mode, the response of these structures is dominated by their electric or magnetic dipole moment. In either case, this results in strong reflection at the resonant frequency due to impedance mismatch of the sample with the surrounding medium. In addition, the resonant optical activity in such structures is accompanied by strong circular dichroism, causing ellipticity of the output polarization state, which is often undesirable.3 In conducting a thorough search of the relevant literature,3–6,9–14 it is found that for all relevant cases this dispersive optical activity occurs. It is possible to achieve reasonably flat optical activity off-resonance; however, this is accompanied by a drop-off in the magnitude of the optical activity.

By combining a meta-atom with its complement in a chiral configuration, we can overcome the impedance mismatch at the resonant frequency as, according to Babinet’s principle, this results in the coupling of an electric dipole type response with a corresponding magnetic dipole type response.15 This results in an impedance matching effect with low reflection at resonance and should also lead to higher transmission. This approach has been used to achieve dual-band ultraslow modes by alternating layers of SRRs and their complementary structures.16 It has also been used to create a broad bandpass filter in the terahertz regime, combining a cross and its complement of different parameters in a non-chiral arrangement, for which the current distributions for the resonant modes were also studied.17

Broadband quarter-wave plate operation was achieved recently by tailoring the resonances of perpendicular nanorods.18 However, this system was operated off-resonance, and in contrast to our system, coupling between the two different resonant elements is negligible.

Here we study a cross coupled to its complement, or a “mixed pair,” and find that our structure provides strong optical activity which resonates away from the transmission resonance, resulting in very low ellipticity at the transmission resonance. We also determine, by looking at the case of a strip combined with a slot, that our structure is excited by means of the hole-modes in the complementary cross. We optimize the chirality through the twist angle and study the effect of changing the spacing between elements.

We choose the cross and its complement to have arms of length of 25 mm and width of 1.5 mm. They are separated by a substrate 1.6 mm thick and rotated through 22.5°. We model them as perfect electrical conductors (PEC), inside a circular waveguide, so as to be experimentally realizable. The substrate has a dielectric constant of 4.3 and loss tangent of 2.5 × 10−4. A schematic of the two elements rotated through an angle θ is shown in Fig. 1. Simulations are performed using CST MICROWAVE STUDIO, using a linearly polarized input wave, where the first two cut-off modes are excited. The first mode is assigned to that with the electric field oriented in the x-direction and the second for the y-direction.

We simulate the co- and cross-polarized transmission coefficients for both linear polarizations (Sxx, Syy, Sxy, and Syx). As our structure has four-fold rotational symmetry, we only need Sxx and Syy. The amplitude of the total transmission (S2xx + S2yy)1/2 is plotted in Fig. 2(a).

Transmission coefficients for circular polarization are found as

$$T_{\pm\pm} = \frac{(S_{xx} + S_{yy}) \mp i(S_{xy} - S_{yx})}{2},$$

where $T_{\pm\pm}$ is the right hand wave, and $T_{-\mp}$ is the left handed wave. From this we then calculate the optical activity as

$$\phi = \frac{\text{arg}(T_{\pm\pm}) - \text{arg}(T_{-\mp}) + 2m\pi}{2},$$

where $m$ is an integer such that $\phi$ is between $-\pi$ and $\pi$. This is plotted in Fig. 2(b) (solid black curve). We show the corresponding ellipticity, in Fig. 2(c) (solid black curve), which is calculated as

$$\eta = \frac{1}{2} \tan^{-1} \frac{|T_{\pm\pm}|^2 - |T_{-\mp}|^2}{|T_{\pm\pm}|^2 + |T_{-\mp}|^2}.$$
The corresponding ellipticities, calculated using Eq. (3), are shown in Fig. 2(c). The ellipticity corresponds to the gradient of the optical activity shown in Fig. 2(b). This means that unlike the other two structures, our mixed structure has very low ellipticity at resonance, which is very desirable. It also shows much lower ellipticity overall than the other structures.

In order to determine the nature of the transmission resonances of this structure, we study the excitation of a single strip and slot. We choose to do this as the slot-strip system is a simpler structure than our “mixed pair” and is also anisotropic but exhibits qualitatively similar behavior as our structure. It allows us to determine which coupling mechanisms contribute to the response in our system. We align the slot along the y-axis and then add the strip aligned either in a parallel or perpendicular configuration, as shown in Fig. 3(a). We use strips of the same length and width as the crosses above, along with the same substrate, resulting in a transmission peak in the same frequency range. Fig. 3(b) shows the through transmission for both incoming polarizations, for the parallel configuration of this setup. The same results, but for the perpendicular arrangement, are shown in Fig. 3(c).

We see that for both arrangements (Figs. 3(b) and 3(c)), significant transmission is only seen when the incoming polarization is across the slot ($S_{xy}$). It should be noted that these graphs are plotted using a log scale, so it can be seen that the transmission for the wave polarized along the slot ($S_{yx}$) is almost negligible. By looking at these results, we can conclude that the predominant mechanism in exciting this structure is through the hole-mode in the slot. The strip is excited by the electric field parallel to it. As the strip is rotated from parallel to perpendicular to the slot, the strength of its excitation changes. This then couples to the excitation of the slot to determine the properties of the resonance.

We can then conclude that the predominant excitation in our structure is through the hole-mode in the complementary structure aligned perpendicular to the magnetic field, which then couples primarily to the perpendicular corresponding arm of the cross.

As the transmission resonances are similar in the chiral and achiral configurations, we now study the effect of introducing chirality through the twist angle $\theta$. We measure the transmission for $\theta$ ranging from $0^\circ$ to $45^\circ$, in $2.5^\circ$ increments. In Fig. 4(a) we show the total transmission for a few of these angles. We see that as $\theta$ is increased, the resonance increases, and the transmission height changes slightly, but the effect of $\theta$ on the transmission is not huge. Fig. 4(b) shows the optical activity at the resonance frequency, as a function of twist angle $\theta$. We see that the near-field coupling within a twisted “mixed pair” leads to changing optical activity due to change in the coupling between the two elements. While this structure has maximum asymmetry at $\theta = 22.5^\circ$, we find maximum optical activity of $\phi = 22^\circ$ at $\theta = 17.5^\circ$. This is due to retardation, as shown in Ref. 19. The resonant behavior at $3.5$ GHz, associated with the stop-band resonance in the transmission, is present for most values of $\theta$ and is less tunable. The ellipticity at resonance was also calculated and shows a similar trend (not shown here), peaking at $0.1^\circ$.

By changing the distance between the cross and its complement, we change the retardation in the structure, as well as the interaction between the resonators. From Fig. 5(a) we see that by increasing the spacing between the elements, we significantly reduce the magnitude of the transmission. More importantly, the transmission resonance shifts closer to the optical activity resonance, therefore increasing the ellipticity of the structure across the transmission band. However, we also see a decrease in the magnitude of the optical activity as the spacing is decreased. Therefore we conclude that we have a trade-off between the magnitudes of the transmission and optical activity, in choosing the optimal spacing.

In conclusion, we have proposed a “mixed pair” structure, which is a combination of a meta-atom with its complement and found large, flat optical activity at resonance, accompanied by very low ellipticity. We have also shown how this structure is excited and how these effects can be optimized by changing the twist angle $\theta$ and the spacing between the elements.
